

giving updates, we report it in [Section A.6](#).

still had a very regular transition rule. We therefore asked to give a less regular rule containing several kinds of operations. We moved to mixed register programs containing addition, XOR, and multiplication. We scored each local transition from the state actually seen. A mistake could not make a later correct update appear wrong. We averaged over self-fed executions over 32 steps.

On a single update correctly about 89% of the time. Yet [Figure 1](#) shows that over 31 self-fed updates, complete horizon-32 accuracy drops to 25% chance rate; one-pass reasoning reaches 5.83%.

These results show that local transition competence from accumulated reliability is not independent, and adding a fifth code bit did not repair it, ruling out
