

control in Figure 5 holds optimization exposure fixed, ruling out the cause of the distinct-example trend. The left-hand control holds the right-hand control before isolates source-problem diversity from nominal dataset size. Another explanation: the adapters trained on more diverse datasets improve the model more. Retaining 90% of a larger improvement may improve performance more. We are asked how to separate source information from the amount of source information.

Information control

do not come with a known number of information bits, a failure is measured on a poor information proxy. To counteract this, we try to find a task where the source information is known by construction. For this, we consider the task of predicting the last bit of a binary sequence of length n from the first $n-1$ bits. This task is known to be information-theoretically optimal for predicting the last bit of a binary sequence of length n from the first $n-1$ bits. We use this task to evaluate the performance of the different methods. The results are shown in Table 1. The results show that the proposed method outperforms the other methods in terms of information bits per sample. This is due to the fact that the proposed method is able to extract more information from the data than the other methods. The results also show that the proposed method is able to predict the last bit of a binary sequence of length n from the first $n-1$ bits with a higher accuracy than the other methods. This is due to the fact that the proposed method is able to extract more information from the data than the other methods.
